Abstract The purpose of this study was to compare measurements of hepatic tissue blood flow (TBF) calculated by xenon and perfusion CT. Seven patients with normal liver and eight with chronic liver disease underwent both xenon and perfusion CT. During xenon CT examinations, serial abdominal CT scans were obtained every minute before and during 4 min of nonradioactive 25% (v/v) xenon gas inhalation and 5 min of administration of oxygen-rich air. Hepatic arterial and portal venous TBF were measured separately with a special imaging system using the Kety-Schmidt expression based on the Fick principle (AZ-7000W; Anzai Medical Co.). The hepatic arterial fraction (HAF) was calculated as follows: [hepatic arterial TBF/(hepatic arterial TBF + portal venous TBF)]. During perfusion CT examinations, total hepatic TBF and HAF were also calculated from the enhanced CT cine image data on a workstation using a commercially available software package based on a deconvolution algorithm (CT Perfusion 3 GE Healthcare, USA). Total hepatic TBF measured by xenon and perfusion CT was 82.9 ± 15 and 82.8 ± 18 ml/min/100 g, respectively. The measured values

by the two techniques showed a significant correlation ($R^2 = 0.657$, $P < 0.05$). HAF measured by xenon and perfusion CT was 26.6 ± 11 and $21.8 \pm 13\%$, respectively. The measured values by the two techniques also showed a significant correlation ($R^2 = 0.869$, $P < 0.05$). We conclude that there was a good correlation between hepatic TBF quantified by xenon CT and perfusion CT.

Introduction

In chronic liver disease, high intrahepatic vascular resistance decreases the portal fraction of liver perfusion [1, 2]. This decrease in portal perfusion is partially compensated by an increase in arterial inflow [1, 3, 4]. These hemodynamic changes in cirrhosis have a profound effect on hepatic function and could be useful for a precise and objective diagnosis. Various methods exist for the measurement of hepatic perfusion [5–9], however, the majority of these methods are controversial [5, 10].

Previous reports indicated that xenon computed tomography (CT) could provide quantitative measurement of hepatic tissue blood flow (TBF) [11, 12]. However, the application of xenon CT requires special equipment and materials, such as nonradioactive xenon gas. Recently, some studies have demonstrated the capacity of perfusion CT to evaluate hepatic TBF [13–16]. The application of perfusion CT requires only a workstation with perfusion analyzing software. Therefore, we hypothesized that if a good correlation between xenon CT and perfusion CT, in hepatic TBF, could

be demonstrated, xenon CT could be replaced with perfusion CT for quantification of hepatic TBF.

The purpose of this study was to evaluate the correlation between hepatic TBF calculated with xenon CT and perfusion CT, based on a deconvolution algorithm.

Materials and Methods

Patients

Seven patients without liver disease (four females, three males; age range, 24–58 years; mean age, 39.6 ± 12 years [SD]) and eight patients with chronic liver diseases (four females, four males; age range, 48–68 years; mean age, 57.1 ± 8 years) underwent both xenon and perfusion CT examinations from April 2003 to January 2004. Three of the eight patients with chronic liver disease had living donor liver transplantation, and the other five had liver tumors (hepatocellular carcinoma [HCC], three cases; cholangiocarcinoma [CCC], two cases) underwent hepatectomies. With regard to the Child-Pugh classification, five patients were classified as Child A, one as Child B, and two as Child C. The seven patients without liver disease were donor candidates for living liver transplantation; the diagnosis of normal liver was confirmed by needle biopsy history, physical examination, laboratory screening, and Doppler sonography of the liver.

All patients provided informed consent to undergo the enhanced CT, xenon CT, and perfusion CT examinations and to be included in the study, which was conducted in accordance with the principles of the Declaration of Helsinki [17]. Approval from our Ethics Committee was not required for this study.

Xenon CT technique

Xenon CT technique was used to assess regional TBF by using the wash-in/wash-out protocol, used previously for measurement of regional cerebral blood flow [18]. The Kety-Schmidt equation, based on the Fick principle used for cerebral blood flow evaluation, was also used [19, 20]. Xenon gas (Xenon Cold; Anzai Medical Co., Tokyo) was used as the nonradioactive xenon gas, and a xenon gas inhalation system with a closed gas circuit (AZ-725; Anzai Medical Co.) was used. Xenon concentrations in the respiratory circuit (end-tidal peak xenon values) were continuously measured during examination by a xenon monitor incorporated in the AZ-725 circuit. End-tidal peak xenon values were recognized automatically and fitted to a monoexponential curve (end-tidal xenon curve) [21]. Changes in arterial blood xenon concentrations were estimated based on the end-tidal xenon curve [22].

Changes in CT values of the liver parenchyma were measured by an eight-channel multidetector-row CT scanner (LightSpeed Ultra; GE Healthcare, USA). Four axial images with a 10-mm slice thickness including the liver parenchyma around the porta hepatis level were obtained incrementally as baseline CT images prior to xenon inhalation. In the next step, patients inhaled 25% (vol/vol) xenon gas for 4 min (wash-in), then breathed room air for 5 min (wash-out) [18]. CT scans were acquired at each level at 1-min intervals. As many as 10 CT images per patient were obtained in total, including the baseline image at each level. Exposure factors were 100 kVp, 200 mA, and 1-sec scans; patients were required to hold their breath for 7 sec during a series of scans at four levels. Smoothing with a 9×9 -pixel filter was used to reduce noise contribution on the CT images. Body movement related to respiration was taken into account, and changes in the pancreatic position on each enhanced CT image were digitally corrected relative to the baseline image on the screen of a blood flow imaging analysis computer (AZ-7000W; Anzai Medical Co.) system.

AZ-7000W was also used to create color maps for hepatic arterial and portal venous TBF (ml/min/100 g) from images obtained by xenon CT as well as confidence images, which showed the variance of value for each pixel based on the least squares method. High TBF appeared as red regions and low TBF as blue regions. Confidence images were used to evaluate the reliability of the TBF value for each pixel of the image [11, 12]. TBF was determined by placing regions of interest (ROI) on the noncancerous region of the liver parenchyma on the color maps. The ROI of the noncancerous region was carefully placed away from the tumors without overlapping visible blood vessels.

The percentage hepatic arterial fraction (HAF) was calculated using the following equations.

$$\begin{aligned} &\text{Hepatic arterial TBF} + \text{Portal venous TBF} \\ &= \text{Total hepatic TBF} \\ &\text{HAF} = (\text{Hepatic arterial TBF} / \text{Total hepatic TBF}) \times 100 \end{aligned}$$

Perfusion CT technique

Perfusion and xenon CT examinations were performed with the same CT scanner. At first, whole-liver images were obtained with a tube voltage of 120 kV, a tube current of 300 mA, a rotation period of 0.5 sec, a detector collimation of 2.5 mm, and a table increment of 27 mm/rotation. Images with an effective section thickness of 5 mm were reconstructed every 5 mm to provide contiguous sections. Then CT perfusion examinations were performed with a cine mode scan (1 sec/rotation) at the level of the porta hepatis, determined by the whole-liver images. The scan parameters employed for CT perfusion study were 120 kV, 60 mA,

1 sec/rotation, 10-mm slice thickness \times 2, cine scan mode, standard reconstruction algorithm, and 35-cm display field of view (DFOV). A dose of 0.5 ml/kg (total dose, 25–40 ml) of 300 mg I/ml of the nonionic contrast medium (Iohexol, Omnipaque; Daiichi Pharmaceutical Co., Tokyo) was injected at a rate of 5 ml/sec through a 20-gauge plastic cannula inserted into the antecubital vein, followed by 30 ml of saline chaser at a rate of 5 ml/sec with a power injector equipped with double syringe drivers. Data acquisition was started 8 sec after the initiation of injection of the contrast medium and the scan duration was 40 sec. Oxygen inhalation (2 L/min) was given to help the patients hold their breath during scanning. Image reconstruction was performed every 0.5 sec, and these images were transferred to the image processing workstation (Advantage Workstation 4.1; GE Healthcare), to calculate color map images of each blood flow parameter in the liver parenchyma by using commercially available software (CT Perfusion 3; GE Healthcare). Blood flow parameters included TBF (ml/min/100 g) and HAF (%). To calculate each functional map image, ROIs (pixel size, 8–20 pixels) were set on the aorta and portal vein trunk as input function. At the time of measuring the parameters, one radiologist with 15 years' experience in gastrointestinal and hepatobiliary imaging carefully placed 10–20 ROIs (pixel size; \sim 400 pixels) in each section of the liver by avoiding intrahepatic large vessels or tumors confirmed on a CT image (Fig. 1). The value of all ROIs was measured and averaged for each case (Fig. 2b). In our study, ROIs of the liver parenchyma in patients with HCC were drawn in a nontumor segment in order

to avoid direct mechanical compression of portal radicles and the influence of arteriovenous shunt.

Statistical analysis

Differences in TBF and HAF calculated by xenon and perfusion CT were analyzed using regression analysis. Data are expressed as mean \pm SD. Statistical significance was defined as a *P* value of < 0.05 .

Results

In all cases, total hepatic TBF calculated by xenon and perfusion CT was 82.9 ± 15 and 82.8 ± 18 ml/min/100 g, respectively (Table 1). HAF calculated by xenon and perfusion CT was $26.5 \pm 11\%$ and $21.8 \pm 13\%$, respectively (Table 1). Linear regression analysis showed a good correlation in the measurements of both total hepatic TBF ($y = 0.936x + 3.666$; $R^2 = 0.657$, $P < 0.05$) and HAF ($y = 1.056x - 6.632$; $R^2 = 0.869$; $P < 0.05$) calculated by xenon CT and perfusion CT (Fig. 3).

In patients without liver disease, total hepatic TBF calculated by xenon CT and perfusion CT was 85.7 ± 10 and 88.7 ± 17 ml/min/100 g, respectively (Table 1). HAF calculated by xenon CT and perfusion CT was 23.1 ± 5 and $20.6 \pm 6\%$, respectively (Table 1). Linear regression analysis showed a good correlation in the measurements of both total hepatic TBF ($y = 1.411x - 32.283$; $R^2 = 0.711$, $P < 0.05$)

97.0 ml/min/100 g; hepatic arterial TBF, 21.0 ml/min/100 g; portal venous TBF, 76.0 ml/min/100 g; and hepatic arterial fraction (HAF), 22%. (b) Perfusion CT images. Left: Total hepatic TBF image. Right: HAF image. Total hepatic TBF is 110.7 ml/min/100 g and HAF is 21.0%

and HAF ($y = 0.958x - 1.502$; $R^2 = 0.55$, $P < 0.05$) calculated by xenon CT and perfusion CT (Fig. 4).

In patients with chronic liver disease, total hepatic TBF calculated by xenon CT and perfusion CT was 80.5 ± 18 and 77.6 ± 18 ml/min/100 g, respectively (Table 1). HAF calculated by xenon CT and perfusion CT was $29.6 \pm 14\%$ and

$22.9 \pm 17\%$, respectively (Table 1). Linear regression analysis showed a good correlation in the measurements of both total hepatic TBF ($y = 0.728x + 19.211$; $R^2 = 0.566$, $P < 0.05$) and HAF ($y = 1.17x - 12.115$; $R^2 = 0.936$, $P < 0.05$) calculated by xenon CT and perfusion CT (Fig. 5).

Table 1 Measurement of the hepatic tissue blood flow

	All Patients	Normal liver	Chronic liver disease
<i>n</i>	15	7	8
<i>Xenon CT parameters</i>			
Total hepatic TBF (ml/min/100 g)	82.9 ± 15	85.7 ± 10	80.5 ± 18
Portal venous TBF (ml/min/100 g)	60.7 ± 14	65.7 ± 7	56.4 ± 18
Hepatic arterial TBF (ml/min/100 g)	22.1 ± 11	20.0 ± 6	24.0 ± 14
HAF (%)	26.6 ± 11	23.1 ± 5	29.6 ± 14
<i>Perfusion CT parameters</i>			
Total hepatic TBF (ml/min/100 g)	82.8 ± 18	88.7 ± 17	77.6 ± 18
HAF (%)	21.8 ± 13	20.6 ± 6	22.9 ± 17

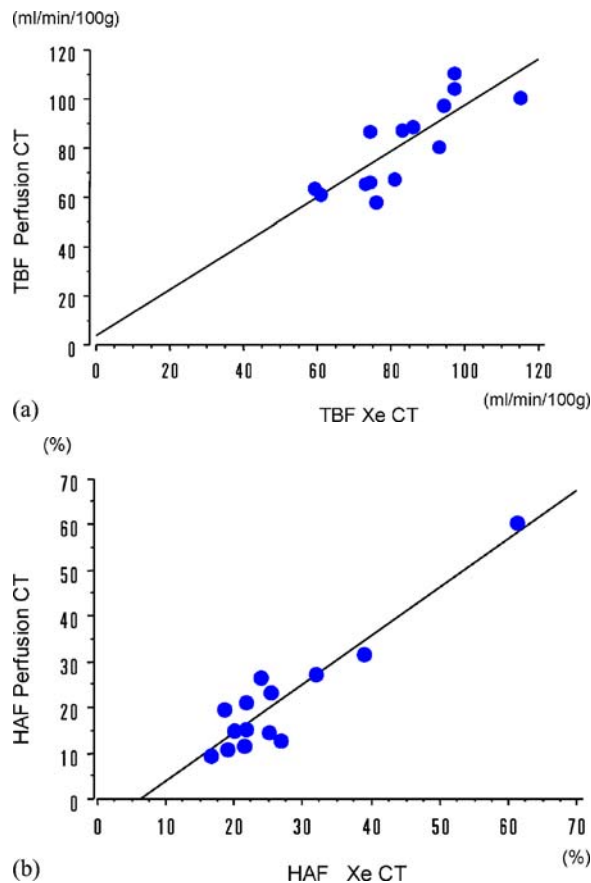

Fig. 3 Total hepatic TBF and HAF measured by xenon CT and perfusion CT in all cases. (a) Correlation between total hepatic TBF perfusion CT and TBF xenon CT. Linear regression analysis shows a good correlation of total hepatic TBF measurements ($y = 0.936x + 3.666$; $R^2 = 0.657$, $P < 0.05$). (b) Correlation between HAF perfusion CT and HAF xenon CT. Linear regression analysis shows a good correlation of HAF measurements ($y = 1.056x - 6.632$; $R^2 = 0.869$, $P < 0.05$)

Discussion

Quantitative measurement of hepatic TBF, using various methods such as isotope scintigraphy [8], Doppler ultrasound [9], xenon CT [11, 12], and perfusion CT [13–16], has been reported. Among these methods, the nuclear medicine approach has the longest history and is regarded as the gold standard for cerebral blood flow [23]. However, a limitation of this method is that nuclear medicine approaches such as positron emission tomography (PET) and single photon emission tomography (SPECT) require radioisotopes and special equipment that are very expensive. Moreover, the spatial resolution of these imaging modalities is inferior to that of CT. The application of magnetic resonance imaging (MRI), is associated with difficulties in the quantification of TBF, because signal enhancement of vessels and tissue by nonspecific MR contrast medium, such as gadolinium complex, does not show a linear correlation with the concentration of the contrast medium [24]. CT provides much

(a) Linear regression analysis of TBF perfusion CT and TBF xenon CT showing a good correlation of hepatic TBF measurements ($y = 1.411x - 32.283$; $R^2 = 0.711$, $P < 0.05$). (b) Linear regression analysis of HAF perfusion CT and HAF xenon CT. Linear regression analysis also shows a good correlation of HAF measurements ($y = 0.958x - 1.502$; $R^2 = 0.55$, $P < 0.05$)

clearer and sharper images than other modalities and can be used to evaluate simultaneously color maps of quantitative TBF and clear anatomical images. In addition, CT is the most practical and universal machine on clinical sites and is used frequently for abdominal scans.

There are two methods available for calculation of TBF with CT: xenon and perfusion CT. Xenon CT has been in clinical use for approximately 30 years [25], and perfusion CT was first described by Miles in 1991 [26]. Patients have to hold their breath for a relatively long time at the same level of respiratory cycle in order to have useful CT data for precise calculation of hepatic TBF. However, recent technical innovations in CT, such as fast imaging ability, have overcome this limitation by reducing the breath-holding duration. However, xenon CT might not be practical, given its requirement for excellent collaboration from patients, in addition to special materials such as xenon gas and specialized equipment. Xenon gas may occasionally be responsible for a decrease in respiratory rate, headaches, nausea, vomiting,

Fig. 5 Total hepatic TBF and HAF measured by xenon CT and perfusion CT in patients with chronic liver disease. (a) Linear regression analysis of TBF perfusion CT and TBF xenon CT showing a good correlation of total hepatic TBF measurements ($y = 0.728x + 19.211$; $R^2 = 0.566$, $P < 0.05$). (b) Linear regression analysis of HAF perfusion CT and HAF xenon CT. Linear regression analysis also shows a good correlation of HAF measurements ($y = 1.17x - 12.115$, $R^2 = 0.936$, $P < 0.05$)

and convulsions [27]. However, there have been no reports of respiratory failure. A large study involving 1839 patients reported that 3.6%, 0.4%, 0.2%, and 0.2% of patients experienced xenon side effects of decreased respiratory rate, headaches, nausea, vomiting, and convulsions, respectively [27].

Compared with the complexity of xenon CT, perfusion CT requires only universal materials to measure blood flow, such as small amounts of iodine contrast material, except for a workstation with the CT perfusion analyzing software. Moreover, perfusion CT can be performed in the same clinical session, immediately before the usual dynamic CT with iodine contrast medium. In this study, the fast imaging ability of multidetector CT provided high-quality images that also contributed to precise measurement of blood flow with decreasing noise. For these reasons, we considered perfusion CT to be significantly more practical than xenon CT. This study demonstrated that total hepatic TBF and HAF mea-

sured by perfusion CT show a good correlation with data from xenon CT.

In the procedure of perfusion CT, the past method using the Fick principle requires injection rates, as high as 10–20 ml/sec, of contrast material via a peripheral vein and, thus, can be very dangerous in patients with fragile or thin vessels [13]. However, the new perfusion technique using the central volume principle with a deconvolution algorithm, employed in this study, needs an injection rate of only 3–5 ml/sec, which is the normal rate in routine work and is much safer than previous methods [15].

Under the present conditions, there were some limitations of this study. Because the aorta and the portal vein should always be included in the scan section for the calculation process and a maximum width of 20 mm could be scanned in cine mode, the examination range was limited to the porta hepatis. However, wider detectors such as those of 32 to 40 mm that are available in the newest multidetector-row CT model with a greater number of detector rows can overcome this limitation. Although we used low-dose x-rays for the perfusion CT study, doses of radiation exposure to patients can increase. It is expected that this can be reduced by new techniques such as the quantum noise filter [28].

In conclusion, xenon CT and perfusion CT showed a good correlation for measurements of total hepatic TBF and HAF. We expect that perfusion CT, based on the deconvolution algorithm, could replace xenon CT for measurement of hepatic TBF.
